1 **Abstract**

2 **Objectives:**

3 To assess the position of the conus medullaris (CM) at first trimester 3D ultrasound in a cohort of  
4 structurally normal fetuses.

5 **Methods:**

6 This was a multicenter prospective study involving a consecutive series of structurally normal fetuses  
7 between 11 – 13 weeks of gestation (CRL between 45 – 84 mm). All fetuses were submitted to 3D  
8 transvaginal ultrasound using a sagittal view of the spine as the starting plane of acquisition. At  
9 offline analysis, the position of the conus medullaris was evaluated by two independent operators  
10 with a quantitative and a qualitative method: 1) the distance between the most caudal part of the  
11 conus medullaris to the distal end of the coccyx (CMCd) was measured; 2) a line perpendicular to the  
12 fetal spine joining the tip of the conus medullaris to the anterior abdominal wall was traced to  
13 determine the level of this line in relation to the umbilical cord insertion (Conus to-abdomen-line or  
14 CAL). Interobserver agreement for the CCMd was evaluated. Linear regression analysis was used to  
15 determine the association between CMCd and CRL and a normal range was computed based on the  
16 best-fit model. The absence of congenital anomalies was confirmed in all cases after birth.

17 **Results:**

18 In the study period between December 2019 and March 2020, 143 fetuses were recruited. In 130  
19 fetuses (90.9%), the visualization of the CM was feasible. The mean value of the CMCd was  $1.09 \pm$   
20  $0.16$  cm. The 95% limits of agreement for the interobserver variability in measurement of the CMCd  
21 were  $-0.24$  and  $0.26$  cm. The interobserver variability based on the ICC for the CCMd was good (ICC=  
22  $0.81$ ). We found a positive linear relationship between the CCMd and the CRL. In all these fetuses,  
23 the CAL encountered the abdominal wall at or above the level of the cord insertion.

24 **Conclusion:**

25 In normal fetuses the assessment of the conus medullaris position is feasible at first trimester 3D  
26 ultrasound with a good interobserver agreement. The CM level was never found below the fetal  
27 umbilical cord insertion, while the CMCd was noted to increase according to the gestational age,  
28 confirming the “ascension” of the CM during fetal life.

29

## 30 **Introduction**

31 Closed spinal dysraphism (CSD) is an abnormality of the posterior arch formation in which the defect  
32 is covered by the skin (1). The prevalence of CSD is estimated to be 2 – 4 in 1000 live births (2,3). The  
33 clinical manifestations of the CSD may vary between the absence of symptoms and severe  
34 neurologic, genitourinary, gastrointestinal and musculoskeletal anomalies. The most common  
35 pathological condition associated with CSD is represented by the tethered cord syndrome, which is  
36 associated with the pathological elongation of the distal part of the conus medullaris (CM) due to its  
37 anchorage to the surrounding tissues (1,4,5).

38 The prenatal diagnosis of CSD is challenging even in expert hands, with only few cases reported so far  
39 mainly during the 2nd trimester and associated with a subcutaneous mass or a cyst (6,7). CSD  
40 without a subcutaneous mass is mostly reported in the postnatal imaging literature (8,9,10). This is  
41 mainly because of the absence of a visible defect at the level of the lumbar spinal cord and indirect  
42 cranial signs of spinal dysraphism (6). Based on the “ascension” of the CM during the fetal period,  
43 which is described by the elevation of the conus medullaris from the sacral position up to the level of  
44 the second lumbar vertebra at birth (11-13), some authors have hypothesized that the caudal  
45 displacement of the conus medullaris may represent an indirect sign of CSD. An unusually low  
46 position of the CM could therefore raise the suspicion of a tethered cord syndrome indicating a lack  
47 of ascent of the CM in the spinal canal (4,12,14). However, the standard prenatal ultrasound  
48 assessment of the position of the CM is not performed on a routine basis.

49 Several studies have attempted to describe the position of the CM prenatally in a quantitative or a  
50 qualitative manner in order to establish the normal level of the CM at different gestational ages.  
51 Among the different approaches proposed, the measurement of the distance of the CM from the  
52 coccyx and the evaluation of the position of the CM in relation to a lumbar level have been  
53 attempted mainly in the second and third trimesters (11,12,14,17-22). To the best of our knowledge  
54 no study has so far evaluated the normal position of the CM between 11+0 and 13+6 weeks of  
55 gestation. We therefore conducted a multicenter prospective study to assess the position of the  
56 conus medullaris at first trimester 3D ultrasound in a cohort of normal fetuses.

57

## 58 **Materials and Methods**

59 This was a multicenter prospective study conducted between November 2019 and February 2020  
60 and involving 2 Centers of Prenatal Diagnosis in Italy, the University Hospital of Parma, and the  
61 University Hospital of Insubria. The recruitment was stopped earlier after 4 months due to the Covid-  
62 19 pandemic. All pregnant women gave written consent to participate before the scan. The study  
63 was approved by the local ethics committee (561/2018).

64 The inclusion criteria were as follows: singleton pregnancy, gestational age between 11+0 – 13+6  
65 weeks (CRL between 45 – 84 mm), normal nuchal translucency (NT) and no obvious fetal  
66 abnormalities at ultrasound examination. Cases where it was not possible to obtain a high-quality 3D  
67 volume of the fetal spine, or it was not possible to identify the CM and the last vertebral body were  
68 excluded from further analysis.

69 All ultrasonography examinations were performed by sonographers with competence on first  
70 trimester ultrasound as certified by the Fetal Medicine Foundation, London. Ultrasonography was  
71 performed using a Samsung W10 Hera System ultrasound machine, equipped with a 4-8 Mhz 3D  
72 endocavitary Samsung Medison Co. Ltd., Seoul, South Korea). First a midsagittal longitudinal plane of  
73 the fetal spine facing anteriorly, focusing on the most caudal part of the spine, was obtained  
74 transvaginally. High quality three-dimensional ultrasound volumes were acquired and stored for  
75 offline processing. The volumes were not acquired if the fetus was in a hyperflexed or hyperextended  
76 state.

77 Offline analysis of the volumes was carried out by two operators (N.V. and G.B.L.S.). N.V. analyzed all  
78 the 143 3D-images, while G.B.L.S. evaluated only the first 40 3D-images. On the midsagittal plane the  
79 CM was visualized as a hypoechoic triangular structure at the caudal end of the spinal cord. The  
80 position of the CM was evaluated using two approaches: 1) On the midsagittal plane we measured  
81 quantitatively the distance between the most caudal part of the conus medullaris and the distal end  
82 of the coccyx (CMCd); 2) while navigating on the 3D multiplanar volume acquired, we compared  
83 qualitatively the level of the CM in relation to the umbilical cord insertion by tracing a line  
84 perpendicular to the fetal spine joining the tip of the conus medullaris to the anterior abdominal wall  
85 (Conus-to-abdomen line or CAL) (Figure 1).

## 86 **Statistical analysis**

87 Statistical analysis was performed using Statistical Package for Social Sciences (SPSS) v. 22 (IBM Inc.,  
88 Armonk, NY, USA). Data were shown as mean + standard deviation. The 95% CI for each continuous

89 variable was also calculated. The Kolmogorov–Smirnov test was used to assess the normality of the  
90 distribution of the data.

91 Interobserver variability of the CMCD was assessed by Bland-Altman plots with 95% limits of  
92 agreement (LOA) and by the intraclass correlation coefficient (ICC). For interobserver variability, the  
93 first 40 measurements were repeated by both operators and compared using both methods. The ICC  
94 was interpreted as an indicator of excellent ( $> 0.90$ ), good ( $0.75\text{--}0.90$ ), moderate ( $0.50\text{--}0.75$ ), or poor  
95 ( $< 0.50$ ) agreement.

96 Linear regression analysis and Spearman's and Pearson's correlations were used to evaluate the  
97 correlation of the CCMd as a function of CRL.  $p < 0.05$  was considered as statistically significant.

98 **Results**

99 We screened 172 patients for eligibility, from which 29 were excluded due to maternal or fetal  
100 reasons (Figure 2). Overall, 3D US volumes of 143 consecutive fetuses were obtained, among whom  
101 the CM position could be successfully evaluated in 130 consecutive, structurally normal fetuses, all of  
102 which were included in this study. The remaining 13 cases did not meet the inclusion criteria, for  
103 different reasons such as persistently unfavorable fetal position (spine down) or inadequate volume  
104 acquisition and were excluded from further analysis (Figure 2). The absence of fetal structural defects  
105 and particularly of spine abnormalities was confirmed at postnatal assessment for all the included  
106 cases.

107 The mean gestational age (GA) at enrolment was  $12+3\pm 0+4$  weeks with a mean CRL of  $62.91 \pm 7.65$   
108 mm. Table 1 summarizes the maternal characteristics.

109 At quantitative assessment, the CCMd followed a normal distribution (Figure 3) and its mean value  
110 was  $1.09 \pm 0.16$  (95% CI 1.062 – 1.118) cm. Linear regression analysis showed a correlation between  
111 the CCMd and the CRL (Pearson's correlation coefficient  $r = 0.24$ ,  $p = 0.006$ ; and Spearman's  
112 correlations coefficient  $r = 0.27$ ,  $p = 0.002$ ). The best-fit formula between CMCd and CRL was as  
113 follows:  $CCMd = 0.0051 \times CRL + 0.7715$ . Figure 4 shows the normal range together with the 5th and  
114 95th percentiles.

115 The mean difference in the CMCd among the 40 repeated measurements of both operators was 0.01  
116 mm (95% LOA, -0.24 to 0.26 cm). The Bland-Altman plot is shown in Figure 5. The ICC value for the  
117 CMCd measurement was 0.81, indicating that the interobserver agreement could be considered as  
118 good (Figure 6).

119 At qualitative evaluation, the CAL encountered the abdominal wall at or above the level of the cord  
120 insertion in all the included fetuses.

## 121 **Discussion/Conclusion**

### 122 **Main findings**

123 In our study, we have shown that the evaluation of the position of the CM in the spinal canal is  
124 feasible in roughly the 90% of the cases at expert first trimester 3D-ultrasound.

125 We found a linear direct relationship between the CMCd and CRL, with good interobserver  
126 agreement. Normal values of CMCd according to the CRL have been also defined. Based on our data  
127 it is possible to predict the normal CMCd according to a given CRL and to calculate the 5th and 95th  
128 percentiles of the measurement.

129 Furthermore, the tip of the CM was never found to be below the level of the umbilical cord insertion.  
130

### 131 **Interpretation of study findings and comparison with previous studies**

132 The position of the CM in adults is well documented between L1 and L2, terminating at or above L2-  
133 L3 in more than 98% of cases (23). However, the position of the CM during fetal life is considered to  
134 be more caudal and the time of ascent of the CM to its final position is still a matter of debate.

135 According to the early hypothesis, the CM was thought to ascend to its normal adult level in infancy  
136 (24,25). Since then, this theory has been disputed by some studies involving autopsies and neonatal  
137 imaging, which have shown that the final ascent was already completed at or before birth (26,27).

138 Prenatal studies support the theory that the ascent of the CM begins during the fetal life (11), as the  
139 CM was sonographically imaged at or above the level of L2-L3 in the vast majority of mid-trimester  
140 fetuses in several studies. Robbin et al. (12) evaluated 33 fetuses at 19 weeks of gestations and found  
141 that the position of the CM was at about L2-L3 or higher. Zalel et al. (11) examined 110 fetuses  
142 between 13 and 40 weeks of gestation. They found that in 100% of their fetuses between 13 and 18  
143 weeks of gestation, the CM was at L4 or lower. In 97% of the cases, they reported a shift of the CM  
144 towards L2-L3 between 18 – 24 weeks. The cranial ascension of the CM was continuous throughout  
145 the pregnancy and at term the CM was reported to lie at or above L1-L2. Perlitz et al. (18)

146 demonstrated the CM level in 110 fetuses between 20 and 24 weeks and found that the CM was  
147 between L2 and L3 in 93% of cases. More recently, Zhai et al. (22) came to the same conclusions  
148 observing the CM position in 521 fetuses between 20 and 38 weeks of gestation. In our study, we did  
149 not evaluate the level of the CM in relation to the vertebral level, rather to the level of the cord  
150 insertion on the anterior abdominal wall. The former measurement has been shown to be  
151 inaccurate, because of the mild ossification of the lower spine in the first trimester of gestation (28)  
152 and the small size of the lumbosacral vertebrae, which reduces the accuracy of the determination of

153 the vertebral level. Moreover, a low interobserver concordance of this measurement has been also  
154 reported in prenatal life (20).

155 Different quantitative evaluations of the CM position have been also proposed by some authors in  
156 the second and third trimester. Hoopmann et al. (19) suggested the measurement of the distance  
157 between the CM and the sacrum in 300 pregnant women between 15 weeks of gestation and term;  
158 this case series included 5 cases of skin-covered spina bifida, among whom the distance between the  
159 CM and the sacrum was below the 5th percentile. Hoopman et al. also reported a positive linear  
160 relationship between the measurement and the GA and biometric parameters such as femur length,  
161 head circumference and abdominal circumference. Another study by Mottet et al. (14) evaluated the  
162 distance between S1 and the CM in 194 pregnant women after 17 weeks of gestations showing also a  
163 linear relationship between such measurement and the GA. Consistent results were reported by Zhai  
164 et al. in a cohort of 521 fetuses, among whom the Authors also demonstrated a high interobserver  
165 concordance of the measurement (22). To our knowledge ours is the first study evaluating the  
166 distance between the CM and the coccyx at first trimester ultrasound. In accordance with previous  
167 studies, we found a positive linear relationship between the GA and the CMCd and a high  
168 interobserver concordance. Our study strengthens the theory of the prenatal ascension of the CM, as  
169 it shows a progression of its distance from the coccyx from 11 to 13 weeks of gestation.

170 Additionally, some studies have reported that 3D ultrasound could improve the accuracy of the  
171 measurements used to describe the position of the CM. He et al. (29) found that measuring the fetal  
172 conus distance in a cohort of 468 normal fetuses and 14 fetuses with tethered cord syndrome  
173 between 14 – 40 weeks of gestation by 3D ultrasonography was more accurate and reliable than 2D  
174 ultrasound. Similarly, Lei et al. (17) examined 150 fetuses between 20 to 38 weeks of gestation using  
175 3D ultrasonography concluding that 3D ultrasound may accurately determine the CM vertebral level.

176

### 177 **Clinical implications**

178 There is increasing awareness regarding the antenatal diagnosis of skin-covered spinal dysraphism,  
179 due to its possible association with tethered cord syndrome. Indeed, the prenatal suspicion of a  
180 tethered cord syndrome would allow the most appropriate birth plan for the couple opting for a  
181 conservative management of the pregnancy as early surgical management of the tethered cord is  
182 important to preserve function and avoid irreversible neurological damage (4,5,15,16).

183 CSD can be classified as with or without a subcutaneous mass. CSD with a subcutaneous mass  
184 represents only 18.8% of the CSD, lipomas with a dural defect accounting for 87.4% of the cases (1).

185 Based on this data, the majority of cases of CSD do not show any visible defect on the ultrasound  
186 scan, and a low-lying CM could be the only sign of a CSD with tethered cord syndrome. Therefore,  
187 the use of a quantitative measurement as the CMCd could help us to diagnose reliably a low-lying  
188 CM. At second and third trimester, the measurement of the CMCd has already been shown to have a  
189 higher interobserver concordance than the CM location based on anatomical landmarks (20-22).  
190 However, the measurement of the CMCd in the first trimester requires a high level of expertise, as  
191 the correct identification of the coccyx and of the CM itself is of crucial importance to achieve an  
192 appropriate measurement, also considering the small size of these structures. In this respect, the  
193 addition of 3D ultrasonography can improve the accuracy of the CMCd measurement (17,29). The 3D  
194 multiplanar mode supported by a high-resolution algorithm allows a better visualization the fetal  
195 spine, thus improving the identification of the CM in relation to the bony components of the spine at  
196 1st trimester.

197 In addition to the quantitative measurement, the qualitative evaluation of the CM position in relation  
198 to the vertebral level described in the second or third trimester could be difficult at 11-13 weeks of  
199 gestation as due to the lower ossification of the vertebral bodies the vertebral count may be  
200 challenging in particular in the lumbosacral region (28). Therefore, we have proposed the umbilical  
201 cord insertion as a new landmark to assess the position of the CM, as we believe it allows an easier  
202 and more accurate characterization of the position of the CM compared to the vertebral count. This  
203 new marker could be easily measured when navigating the 3D volume obtained for the CMCd. As  
204 described above, the CM was always found to be above the insertion of the umbilical cord.

205 Therefore, we have established on a qualitative and quantitative basis the expected level of the CM  
206 at first trimester among structurally normal fetuses. Based on the study performed by Hoopmann et  
207 al., which found that all cases of CSD has a CM distance well below the 5th percentile, we  
208 recommend that a CMCd below the 5th percentile should prompt referral to a specialized fetal  
209 medicine center in order to exclude a CSD diagnosis in expert hands. However, a CMCd below the 5th  
210 percentile is not necessarily associated with a tethered cord syndrome since by definition this can be  
211 observed in 5% of normal fetuses.

212 The same recommendation should be made, if the CM is found to be below the umbilical cord  
213 insertion. Further studies at 11 – 13 weeks of gestation including fetuses affected by tethered cord  
214 syndrome are needed to determine the real clinical utility of these two markers and their predictive  
215 value when diagnosing CSD.

216 **Strengths and limitations**

217 The main strengths of our study are its original and prospective design and the large number of  
218 fetuses examined. Our study is also the first study to describe these markers between 11+0 and 13+6  
219 week of gestations and to incorporate the use of 3D ultrasonography to improve its precision.  
220 Another strength of the study is the high interobserver concordance observed.

221 There are also some limitations that must be acknowledged. In first instance, although our results are  
222 in line with previous studies, the exclusion of cases with an unfavorable fetal position or a suboptimal  
223 echogenicity (i.e., high BMI patients) may have introduced selection bias as the values obtained  
224 might not be representative of the whole population. However, among obese women the rate of  
225 technically inadequate ultrasound scans at 1st trimester is higher, and this could negatively influence  
226 our study, by adding fetuses with overlooked malformations to our cohort. Secondly, we  
227 acknowledge that the sonographic assessment of the CM position at first trimester might be  
228 technically challenging and therefore we cannot recommend yet their inclusion on daily routine  
229 examinations. Nevertheless, our study has shown that the measurements are feasible in the hands of  
230 fetal medicine experts, with a success rate of 90,9 %.

231

## 232 **Conclusions**

233 We have shown that the evaluation of the position of the CM is feasible in the first trimester using 3D  
234 ultrasound. In normal cases, the level of the CM was never found to be below the fetal umbilical cord  
235 insertion, whereas the CMCd was noted to increase with advancing gestational age, confirming the  
236 “ascension” of the CM during fetal life. We envisage that our data may contribute to elucidate the  
237 natural history of skin-covered spinal dysraphism and to improve its sonographic detection during  
238 fetal life.

<b>Demographic and Obstetrical Variables</b>	<b>Mean <math>\pm</math> SD</b>
Gestational age at examination (weeks)	12.52 $\pm$ 0.59
Maternal age (years)	32.87 $\pm$ 5.26
Maternal BMI (kg/m <sup>2</sup> )	24.45 $\pm$ 5.96
CRL (mm)	62.91 $\pm$ 7.65

Table 1. Demographic and Obstetrical Variables of the study

## **Reviewer Comments:**

### **Reviewer 1**

1. In the present study, the authors aimed to assess the position of the conus medullaris (CM) at first trimester 3D ultrasound in a cohort of normal fetuses. They found that the assessment of the conus medullaris position was feasible with a good interobserver agreement. In their population, the conus medullaris level was never found below the fetal umbilical cord insertion, while the distance from CM to coccyx (CMCd) was noted to increase according to the gestational age. The idea of the study is interesting. The study however has many limitations. Examining the conus medullaris may have the potential to assess the cord tethering in case of closed spina bifida. Diagnosis of closed spina bifida remain a challenge even in the second and third trimester. In absence of cranial signs, the vast majority of cases pass undiagnosed. Fortunately, almost all cases of closed spina bifida are asymptomatic or have excellent prognosis. Adding a 3D examination of the conus medullaris in the first trimester to improve early diagnosis of this benign malformation to which there is no prenatal intervention is of questionable usefulness, at best.

### **Reply:**

We thank the reviewer for the comment, but we respectfully disagree with him. The reviewer questions the usefulness of our study based on the absence of prenatal intervention for a CSD and on the lack of severity of the disease. Although it is true that most of the cases are asymptomatic and have a good prognosis, there is a certain number of cases, especially those related with tethered cord syndrome, which could be associated with severe neurological, gastrointestinal, genitourinary and musculoskeletal disorders. Moreover, early detection of these cases and prompt surgical management are associated with a better prognosis and preservation of function.

This study is also important for the understanding of the ascension of the CM during the embryonal period, in order to be able to fully understand this complex group of malformations. It has been speculated that the CM starts its cranial ascension prenatally. However, it is unknown when this process starts. Most of the studies have evidenced an ascension of the CM during the 2<sup>nd</sup> and 3<sup>rd</sup> trimester of pregnancy. But no study to date has shown if this ascension is already visible during the first trimester. Our study shows that the CM has already started its ascension during the 11<sup>th</sup> and 14<sup>th</sup> week of pregnancy. The addition of 3D, as previously shown in studies performed in the 2<sup>nd</sup> and 3<sup>rd</sup> trimester, increases the diagnostic accuracy of the position of the CM.

- He S, Ruan J, Wang X, Lyu G, Wei Y, Huang T, Zeng P. Measurement of fetal conus distance with 3D ultrasonography as a reliable prenatal diagnosis method for tethered cord syndrome. *J Obstet Gynaecol.* 2020; **46**: 587-594. doi:[10.1111/jog.14202](https://doi.org/10.1111/jog.14202)

No change has been made to the manuscript.

2. The authors suggest using the 5-95th centile to describe normality. I would be very cautious in suggesting such a recommendation. By definition, 5% of fetuses will lie in the this group. The incidence of a tethered cord is extremely rare, therefore almost all fetuses with CMCd under 5th centile will be normal fetuses.

**Reply:**

We thank the reviewer for comment. We have just established the percentiles for the CMCd in a normal population of fetuses with no structural malformations, which could be used during the first trimester to screen for a low-lying CM. However, a CMCd below the 5<sup>th</sup>

percentile would be normal, by definition, in 5% of normal fetuses, which means that not all cases below the 5<sup>th</sup> percentile are associated with a tethered cord syndrome. Moreover, based on the study by Hoopmann et al. (ref. below), which found that all the cases of CSD had a conus distance well below the 5<sup>th</sup> percentile, we recommend that a value of the CMCd below the 5<sup>th</sup> percentile should prompt referral to a specialized feto-maternal center in order to exclude a CSD diagnosis in expert hands. CMCd should be used as a screening tool but not as a diagnostic tool of CSD.

- Hoopmann M, Abele H, Yazdi B, Schuhmann MU, Kagan KO. Prenatal evaluation of the position of the fetal conus medullaris. *Ultrasound Obstet Gynecol.* 2011; **38(5)**: 548-552. doi:10.1002/uog.8955

The explanation has been added on the clinical implications of the discussion.

3. It is important to add in the results the 18 women excluded due to maternal BMI, although this is an uncommon reason for unsatisfactory endovaginal ultrasound.

**Reply:**

We thank the reviewer for this comment. It is true that high BMI patients are rarely excluded based on an unsatisfactory endovaginal ultrasound. However, it is also well-known that high BMI patients are difficult to scan, including transvaginal scan, and have more chances of an unsatisfactory scan. Based on this, we excluded the patients because we could not be 100% sure that the baby was structurally normal, which could have introduced bias into our study.

4. Statistics:

A) the authors state that they used or planned to use Chi-square test, Fischer exact test to compare categorical variables. Compare what categorical variables between which groups?

**Reply:**

We thank the reviewer for the comment. This was a typing mistake. There are no categorical variables on the study.

The manuscript has been corrected.

B) They also state that they applied T-test for independent samples. Which independent samples do the authors have? They have a single population of healthy fetuses.

**Reply:**

We thank the reviewer for the comment. This was a typing mistake. The continuous variables of the population were shown as mean  $\pm$  standard deviation or as numbers (percentages).

The manuscript has been corrected.

C) There are some relevant assessments for the interobserver evaluations which they did not perform, such as systematic difference.

**Reply:**

We thank the reviewer for this comment, but we respectfully disagree with the reviewer. We used Bland-Altman plots and intraclass correlation coefficient, which are among reliable tests to measure interobserver variability between 2 subjects, and their use is also extremely common in research on obstetric ultrasound.

No change has been made to the manuscript.

5. The authors claim that the cord insertion corresponds to L3-L4. In supporting their claim, they refer to neonatal studies, while they examined fetuses at 11-13 weeks.

**Reply:**

We agree with the reviewer with this comment. No claim has been now made on the vertebral level of the umbilical cord insertion between the 11<sup>th</sup> and 13<sup>th</sup> week of gestation.

We have amended the manuscript accordingly.

6. In the figure that the authors chose to demonstrate the technique, I cannot see the cord insertion, only the arrow.

**Reply:**

We thank the reviewer for the comment. We have added a new picture with a visible CM and cord insertion (Figure 1).

7. In the multiplanar figure, the conus medullaris is not seen.

**Reply:**

We thank the reviewer for this comment. Figure 1 showed only the plane of acquisition of the 3D volume in the multiplanar mode. We have removed the Figure 1 as it did not add anything important to the manuscript.

8. I would recommend attaching a clip to illustrate the technique for the interested reader.

**Reply:**

We thank the reviewer for this comment. A video showing the acquisition of both measurements (CMCd and CAL) on 2D could be added as a supplement to the manuscript, if required by the reviewers. However, a video documenting the 3D volume acquisition and the post-processing analysis and measurements would be difficult to provide.

9. In the abstract they describe the distance CMCd as 1 mm. This is probably an error.

**Reply:**

We thank for the comment. The manuscript has been corrected.

## **Reviewer 2**

1. I congratulate the authors for their interest in this topic and for proposing an easy and reproducible method for the evaluation of the medullary cone.

### **Reply:**

We thank the reviewer for this positive comment. No change has been made to the manuscript.

## 2. FEASIBILITY:

A) Line 126: you mention that evaluation of the position of the medullary cone was feasible in roughly 90% of cases. I suggest not to underline this but to mention the fact that this study is not a feasibility study because the cases were initially selected in a non-consecutive manner and 13/143 cases were not used. Please explain why these 13 cases are excluded from the analysis.

### **Reply:**

We thank the reviewer for this comment. It was in fact a consecutive cohort of structurally normal fetuses. There was a typing mistake on the abstract, where it was cited as a non-consecutive cohort of fetuses. The 13 cases got excluded from the study for different reasons such as persistently unfavorable fetal position (spine down) or inadequate volume acquisition.

We have added the explanation to the results section.

The manuscript has been amended accordingly.

B) In addition, it should be noted that the agreement of the offline analysis measures of the selected images does not match the agreement of the case measures when you have to select the images and then perform these measures. There may be additional bias if images are pre-selected. You must also evaluate the repeatability of the image.

### **Reply:**

We thank the reviewer for this comment. We would like to point out that the first operator reviewed all the 143 pictures, of whom 130 were included in the analysis. For the interobserver variability, the second operator reviewed the first 40 pictures. Both operators excluded the same pictures based on the inclusion criteria. We did not evaluate the intraobserver variability.

The manuscript has been corrected.

C) Most spinal cord syndromes are diagnosed in the third trimester of pregnancy due to the visualization of a fatty mass (lipoma) at the end of the spinal cord, or by the visualization of an increase in cerebrospinal fluid surrounding the conus medullaris as an obstruction. I suggest to develop a little more for the readers all the signs (direct and indirect) that can be encountered in the spinal cord syndrome.

**Reply:**

We thank the reviewer for this comment. We have added more information in the introduction section regarding the different classification of CSD for the interested reader. However, our study focuses more on the position of the conus medullaris as a possible clue for the antenatal diagnosis of the CSD without a subcutaneous mass, where the identification of the anomaly is more challenging because of the absence of a visible defect.

An explanation has been added in the clinical implications section of the discussion.

D) Given the natural variability of the conus medullaris posture, I find it difficult to believe in the usefulness of quantitative measures of the distance between the tip of the conus medullaris and the sacrum in the first trimester of pregnancy. Your quantitative analysis makes it possible to argue about the probable ascent of the tip of the medullary cone during the fetal period, but the diagnostic usefulness of these measurements seems to me to be much debatable.

**Reply:**

We respectfully disagree with the reviewer. The usefulness of the distance between the tip of the CM and the sacrum has been already demonstrated in the 2<sup>nd</sup> and 3<sup>rd</sup> trimester in the identification of a low-lying CM, which could herald a tethered cord syndrome. Hoopmann et al. showed in their study, that in all cases of CSD, the distance of the CM to the sacrum was well below the 5<sup>th</sup> percentile. The early detection of a tethered cord syndrome would allow the most appropriate birth plan and surgical approach for couple opting for a conservative management of the pregnancy as early surgical management of the tethered cord is important to preserve function and avoid irreversible neurological damage.

- Hoopmann M, Abele H, Yazdi B, Schuhmann MU, Kagan KO. Prenatal evaluation of the position of the fetal conus medullaris. *Ultrasound Obstet Gynecol.* 2011; **38(5)**: 548-552. doi:10.1002/uog.8955

No change has been done to the manuscript.
